Diabetes is often associated with psychological complications such as anxiety. The aim of this study was to evaluate the effects of pyrrolidine dithiocarbamate on anxiety of streptozocin-induced diabetic mouse using the open field and the elevated plus maze tests. Confirmed diabetic mice (>16.7 mM/l of blood glucose) were treated with pyrrolidine dithiocarbamate or 0.9% saline for 10 w. After pyrrolidine dithiocarbamate treatment, mice showed a higher % of time retention in open arms and higher percentage of entries in open arms than the diabetic group in the elevated plus maze. However, there were no differences between total distance and average speed in both groups in the open field test. In conclusion, pyrrolidine dithiocarbamate treatment in diabetic mice exerted anxiolytic-like effects. The present study might be suggestive of a novel treatment approach to diabetic anxiety.

**Key words:** Diabetes, anxiety, pyrrolidine dithiocarbamate

Diabetes mellitus (DM) is the most common chronic endocrine metabolic disorder, which almost affect 366 million people in 2011, and predicted a rise to 552 million by 2030[1]. Diabetes is often associated with psychological complications such as anxiety[2,3]. It has been indicated that anxiety and anxiety related disorders are common in type I and II diabetic patients. Anxiety can be defined as an exaggerated emotional and dysfunctional state associated with hyper vigilance and increased behavioral responsiveness to fearful stimuli. Anxiety has been linked with a variety of behavioral variables, including poor disease management, higher health care costs, more days of missed work, which has severe impact on morbidity and mortality[4,5]. However, the underlying mechanisms of anxiety in diabetics still need to be elucidated.

New pathways linking inflammation and psychiatric diseases are discovered[6,7]. An emerging body of evidence suggests that inflammatory mechanisms may contribute to the development of anxiety disorders[8,9]. It has been shown that anxiety patients and rodents exposed to acute stressors both show elevated serum levels of pro-inflammatory cytokines[10-12]. A number of studies have demonstrated increases in inflammatory markers such as tumor necrosis factor-α (TNF-α) and interleukins in anxiety related conditions including panic disorder and obsessive-compulsive disorder as well as anxiety related personality dimensions and diagnoses such as neuroticism and borderline personality disorder[13-15]. Therefore, inflammation is a recognized antecedent and coincident factor when examining the biology of anxiety.

Recent data have shown that phobic anxiety is associated with higher serum concentrations of
adipokines and cytokines in women with diabetes\cite{16}. Serum TNF-α, a marker for inflammation, was found to increase by 1100% in diabetic rats\cite{17}. Chronic diabetes activates microglia and significantly increases pro-inflammatory cytokine levels in the hippocampus\cite{18}. Microglial cells are activated and pro-inflammatory cytokines are induced in the hippocampus of type 2 diabetic rats. All these data indicate that inflammation plays an important role in diabetics.

It has been shown that pyrrolidine dithiocarbamate (PDTC), an inhibitor of the activation of nuclear factor (NF-κB), produced a significant antianxiety like activity in stressed mice and reduced chronic normobaric hypoxia-induced anxiety like behavior in rats\cite{19,20}. The characteristic long term upregulation of hippocampal NF-κB complex in post-traumatic stress disorder (PTSD) like behavioral stress response was normalized by high dose corticosterone and PDTC administered immediately after exposure\cite{21}. However, whether PDTC affects anxiety in diabetics is still unknown. The aim of the present work was to determine the effects of PDTC on behavioral performance in anxiety tests of streptozotocin (STZ) induced diabetic mice.

All experiments were performed according to the guidelines for use and care of laboratory animals and approved by the animal care and use committee (ACUC) of Tongji medical college of Huazhong university of science and technology. Mice were housed in groups of 4 animals per cage (30×19×13 cm) in a controlled environment with a 12 h light and 12 h dark cycle, average temperature of 22±2°, and 62±5% relative humidity with free access to chow and water (except during estimation of fasted blood glucose levels, where mice were fasted overnight). The animals were kept in our animal facility for at least 14 d before experiments.

Twenty-four mice were randomly divided into three groups: control mice, diabetic mice (DM) and diabetic mice with PDTC (PDM). To induce diabetes, mice from the DM and PDM groups received a single intraperitoneal injection of streptozotocin (STZ, 150 mg/kg; Enzo Life Sciences, Ann Arbor, MI, USA) freshly prepared in 5 M sodium citrate, pH 4.5. Fasted blood glucose levels were monitored weekly using a glucometer. Blood was obtained via tail snip. Control mice were
injected with sodium citrate. Only mice with stable glucose levels more than 16.7 mM/l (95%) were considered as diabetic mice.

Two weeks after STZ injection, diabetes was confirmed again in all diabetic animals. Time zero (w 0) was considered the moment of the start of PDTC treatment. PDTC was freshly prepared in 0.9% saline with a concentration of 100 mg/kg and administrated by intraperitoneal injection at 10:00 am every other d for 10 w to animals in the PDM group. In parallel, 0.9% saline was administrated to control mice and DM mice.

Ten weeks after PDTC treatment, behavioral testing was done during the light cycle. Mice were brought to the experimental room in their home cages 1 h before the behavioral experiments to allow acclimatization to the test environment. The behavioral room was kept very quiet to rule out noises, which might influence stress levels of animals. The experimental room was kept at a controlled temperature (22±2). Mice were tested in the open field tests (OPT) and elevated plus maze (EPM) 24 h after the last dosing of vehicle or drug treatment so as to avoid the acute effect of the drugs. Only one test was performed each d to prevent the residual effects of the testing paradigms.

Elevated plus maze was used to test anxiety like behaviors[22]. In brief, the apparatus consisted of a wooden maze with two enclosed arms (35×10×40 cm) and two open arms (35×10×40 cm) that extended from a central platform (5×5 cm) to form a plus sign. The plus-maze apparatus was elevated to a height of 45 cm and placed inside a room free from noise and disturbances. Each mouse was placed on the central platform of the maze facing its head towards an open arm and left undistributed for 10 min. The behavioral parameters, percentage open arm entries, percentage time spent in open arm and total arm entries, were recorded during a 5-min test period. Increased percentage of open arms activity refered to antianxiety effects, while a decrease in activity revealed elevated anxiety like behavior in rodents. Entry into an arm was considered valid only when all four paws of the mouse were inside that arm[23,24]. The animal activities were recorded by a trained observer blind to the treatments. The apparatus was thoroughly cleaned with 70% ethanol after each
trial to avoid the residual effects.

The OPT apparatus consists of a square Plexigals cage (35×35×40 cm) with walls to minimize outside light and noise. The animals were individually placed in the centre of the OFT apparatus and were left to move freely during a 10-min period.

The data are expressed as mean±SEM and results were analyzed by one-way analysis of variance (ANOVA) followed by Dunnett’s t-test. P<0.05 were considered significant statistical analysis the data are expressed as mean±SEM and results. All values were expressed as mean±SEM. The results were statistically analyzed by ANOVA followed by post-hoc Tukey's multiple comparison test. Results were considered significant with an alpha level of 0.05 and were considered to show a tendency between 0.05 and 0.1.

Effect of diabetes and PDTC on body weight and plasma glucose levels, plasma glucose levels were significantly elevated in diabetic mice 2 w after STZ injection, as compared with their initial glucose levels. There was a significant decline in the body weights of STZ-treated mice as compared with their initial body weight. However, chronic PDTC treatment did not affect the body weight and plasma glucose levels, as compared to the diabetic group (P>0.05).

PDTC alleviated diabetes induced anxiety in the elevated plus maze, ten w after PDTC treatment, mice were subjected to the elevated plus maze task as described above. As depicted in (fig. 1). PDM group mice showed the increased tendency to explore open arms of the maze. Moreover, it was found that PDM group mice showed higher percentage of entries and spend less time in open arms as compared with DM group mice. In the open field test (fig. 2), there were no differences in traveled distance and average speed in 10 min among the three groups.

In the present study, we evaluated the effects of PDTC on behavior performance of STZ-induced diabetic mice in anxiety tests. The diabetic mice showed high blood glucose levels. Our findings demonstrated that PDTC treatment changed behavioral profiles in mice with STZ-induced diabetes. It was observed that PDTC treatment produced anxiolytic like effects. These effects were shown in
the EPM by a higher frequency of entries in open arms. Thus, the current finding clearly revealed that PDTC treatment can reverse anxiety-like behavioral abnormality as psychological consequences of diabetes.

It has been reported that the number of people affected with DM has been steadily increasing over the past few decades. Diabetes is often associated with psychological complications such as anxiety, which have severe impact on morbidity and mortality\[25\]. Therefore, anxiety may be a risk factor for diabetic complications\[26-28\]. Streptozotocin induced diabetes is among the most widely used preclinical models. STZ-induced diabetes has shown to elicit anxiety like behavioral deficits in rodents subjected to elevated plus maze, open field test, social interaction and zero maze tests\[29,30\]. Thus, researchers use STZ-induced diabetes to study diabetes induced behavioral effects. Moreover, it is vital to find new targets and new compounds for treating mood disorders comorbid with diabetes.

Recently, it has been shown that NF-κB is involved in CNS functions\[31-33\]. NF-κB, originally discovered in B cells of the immune system, is widespread in neurons in adult brain, notably in the hippocampus, cerebral cortex and amygdala\[34,35\]. Recent studies have shown that NF-κB plays an important role in physiological and pathological functions in neurons of CNS\[36,37\]. It has been reported that NF-κB is involved in chronic neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease\[38,39\]. NF-κB also plays an important role in neurite outgrowth, synaptogenesis and synaptic plasticity\[40\]. The identified NF-κB complexes were primarily p50/p65 heterodimers and also p50/p50 homodimers in CNS. It has been shown that the p50−/− mice showed significantly less defecation, more rearing, and more time spent in the center compartment relative to wild type control mice in an open field. The mutant mice also spent more time investigating a novel object placed in the open field. On the elevated plus maze, p50−/− mice spent more time on the open arms and had increased numbers of open arm entries relative to wild type. Therefore, NF-κB p50-deficient mice show reduced anxiety-like behaviors\[41\]. It has been reported that the expression...
and nuclear translocation of nuclear factor-kappaB (NF-κB) p65 was elevated in the hippocampus and frontal cortex of diabetic mice\textsuperscript{[42,43]}. Inhibition the expression of NF-κB ameliorated memory deficits in diabetic mice\textsuperscript{[44]}. However, whether NF-κB is involved in anxiety-like behavior in diabetes is still unknown. In the present study, we used PDTC, an NF-κB inhibitor, to explore whether NF-κB mediated diabetic anxiety. It was found that diabetic mice after STZ-induced diabetic condition for 12 w exhibited a significant decrease in the percentage of open arm entries, which accorded with previous reports\textsuperscript{[29,45]}. It was interesting that PDTC treatment for 10 w after STZ injection for 2 w reversed anxiety like behavior induced by diabetic condition in mice as detected by elevated plus maze.

In conclusion, the present study utilized elevated plus maze to explore whether PDTC affected the anxiety like behaviors in STZ-induced diabetic mice. It was found that diabetic mice showed a significant increase of anxiety like behaviors, which could be reversed by long term PDTC treatment. The present study gave rise to opportunities for newer therapies that could be developed for anxiety associated with diabetes.
